ABSTRACT
A fundamentally important role of the Web economy is Online Resource Allocation (ORA) from producers to consumers, such as product allocation in E-commerce, job allocation in freelancing platforms, and driver resource allocation in P2P riding services. Since users have the freedom to choose, such allocations are not provided in a forced manner, but usually in forms of personalized recommendation, where users have the right to refuse.

Current recommendation approaches mostly provide allocations to match the preference of each individual user, instead of treating the Web application as a whole economic system where users therein are mutually correlated on the allocations. This lack of global view leads to Pareto inefficiency, i.e., we can actually improve the recommendations by bettering some users while not hurting the others, and it means that the system did not achieve its best possible allocation. This problem is especially severe when the total amount of each resource is limited, so that its allocation to one (set of) user means that other users are left out.

In this paper, we propose Pareto Efficient Economic Recommendation (PEER) – that the system provides the best possible (i.e., Pareto optimal) recommendations, where no user can gain further benefits without hurting the others. To this end, we propose a Multi-Objective Optimization (MOO) framework to maximize the surplus of each user simultaneously, and provide recommendations based on the resulting Pareto optima. To benefit the many existing recommendation algorithms, we further propose a Pareto Improvement Process (PIP) to turn their recommendations into Pareto efficient ones. Experiments on real-world datasets verify that PIP improves existing algorithms on recommendation performance and consumer surplus, while the direct PEER approach gains the best performance on both aspects.

Pareto Efficiency; Online Resource Allocation; Multi-Objective Optimization; Economic Recommendation; Computational Economics

1 INTRODUCTION
With the trending of human activities shifting from offline to online, the Web has turned into a whole unified economic system just like our physical world, where users can accomplish various types of daily tasks conveniently.

Same as our real-world economic system that has been drawing the attention of economists for centuries, an important functionality of the Web is Online Resource Allocation (ORA), which distributes online products or services from producers to consumers at the speed of internet. For example, E-commerce systems like Amazon distribute normal goods from retailers to users, while house sharing applications like Airbnb distribute housing facilities from hosts to guests.

Because users are granted by law the freedom to choose, enforced online resource allocation is not favorable. As a result, such allocation processes are usually conducted implicitly by personalized recommendation [37], which "suggests" the users to choose particular services.

Since the beginning of modern economics, economists have been taking care of the efficiency of economic systems [14]. The key insight is Pareto efficiency, named after economist Vilfredo Pareto (1906) [32] – one of the pioneers of microeconomics, who is also famous for his "80/20 rule" derived from this concept. Pareto efficiency claims that an efficient system should be one in such an optimal status – that no one can gain further benefits without hurting the others. If a system is not Pareto efficient, we can promote it by Pareto improvements – to increase the benefits of some users while not decreasing the others – until the system is efficient.

Pareto efficiency is widely considered not only in economic analysis [12], but in various engineering tasks, e.g., electric power distribution [47], network bandwidth allocation [50], and task scheduling in cloud computing systems [45], etc.

However, though as a major form of service allocation on the Web, current recommender systems seldom consider whether the allocations are Pareto efficient or not in an economic sense. Basically, both the content-based [33] and Collaborative Filtering (CF)-based [11, 19] approaches attempt to maximize the degree that user preferences are matched by the recommended items [37], rather than viewing the Web economy as a whole, where the benefits of different users can be mutually correlated. This results in the Pareto inefficiency of the recommendations – that the system is not sufficiently optimized to reach the best status, so that it is still possible to benefit the experience of some users without hurting the others.

In this work, we propose Pareto Efficient Economic Recommendation (PEER) for optimal online resource allocation. With solid economic theories and real-world user behavior records, we estimate the per-user utility and surplus on each item to measure the
Although their provided recommendation results may not be Pareto price, thus the surplus forcing a person who is full to consume an additional bread. /this e.g. Utility of the money, and it is the basic concept that serves as the underpinning portfolio of goods or services. Utility can be measured in terms of In economics, utility 2.1 Utility and Surplus the theoretical basis of our framework.

In this section, we formally introduce the key concepts of utility, Section 8. We present the related work in Section 7 and conclusions in Section 6. We further propose a Pareto Improvement Process (PIP) on top of any given recommendation algorithm, which promotes the recommendation results to Pareto efficient ones by Pareto improvements.

Results on real-world E-commerce datasets show that, PIP increases both the recommendation performance and allocation efficiency of traditional recommendation algorithms, while a direct PEER approach gains the best performance on both aspects.

In the rest of the paper, Section 2 introduces some basic concepts for the work. In Section 3 we propose our Pareto efficient economic recommendation framework based on MOO, and in Section 4, we further provide the Pareto improvement process to boost the efficiency of existing recommendation algorithms. Some discussions are made in Section 5, with experimental results provided in Section 6. We present the related work in Section 7 and conclusions in Section 8.

2 BASIC CONCEPTS AND DEFINITIONS

In this section, we formally introduce the key concepts of utility, surplus, and Pareto efficiency from economics, which will serve as the theoretical basis of our framework.

2.1 Utility and Surplus

In economics, utility measures one’s satisfaction over one or a portfolio of goods or services. Utility can be measured in terms of money, and it is the basic concept that serves as the underpinning of the rational choice theory [10].

Utility $U(q)$ is usually a function of the consumption quantity $q$, and is inherently governed by the Law Of Diminishing Marginal Utility [38], which states that as a person increases the consumption of a product, there is a decline in the marginal utility that he derives from consuming each additional unit of the product, e.g., when forcing a person who is full to consume an additional bread. This gives $U''(q) < 0$, while the marginal utility $U'(q) > 0$.

Economists have introduced various forms for utility, for example, the most representative King-Flosser-Rebelo (KPR) utility:

$$U(q) = a \ln(1 + q)$$

(1)

where the parameter $a$ measures the risk aversion as well as the overall lift of the curve.

Based on the theories of rational choice, a consumer would purchase a product/service only if she thinks that the utility she gains from the product is higher than the price that she has to pay, and surplus measures the extra amount of satisfaction she gains beyond the paid price in the transaction. Let $P$ be the per-product price, thus the surplus $S(q)$ is:

$$S(q) = U(q) - P \cdot q$$

(2)

In modern economics, the concept of surplus has solid theoretical origins from the supply-demand economic analysis framework [5, 6], and it is adopted to quantify the benefits of consumers in economic systems.

2.2 Multi-Objective Optimization

Multi-Objective Optimization (MOO) originally grew out of three areas [28]: economic equilibrium and welfare theories, game theory, and pure mathematics. The mathematical and economic approaches to MOO were united with the inception of game theory by Borel in 1921 [44]. The general MOO problem is posed as follows:

$$\max_{x} \{F_1(x), F_2(x), \ldots, F_k(x)\}$$

s.t. $g_r(x) \leq 0, \ r = 1, 2, \ldots, s$

$$h_l(x) = 0, \ l = 1, 2, \ldots, e$$

(3)

where $k$ is the number of objective functions, $s$ is the number of inequality constraints, and $e$ is the number of equality constraints. $x \in \mathbb{R}^n$ is a vector of decision variables, and $F(x) \in \mathbb{R}^k$ is a vector of objective functions $F_i(x): \mathbb{R}^n \to \mathbb{R}$. All vectors are column vectors, and any comparison ($\leq, \geq, \text{etc.}$) of vectors applies to each element.

The objective functions $F_i(x)$ in multi-objective optimization problems are usually mutually correlated, so that the increase on one objective may lead to the decrease of another. As a result, given an MOO problem, we are usually interested in its Pareto efficient solutions, which are introduced in the following subsection.

2.3 Pareto Efficiency and Improvement

Different from single-objective optimization, there is typically no single global solution to an MOO problem. Usually there exist a set of points that all fit a predetermined definition for an optimum. The predominant concept in defining an optimal point is Pareto efficiency (or Pareto optimal) (Pareto 1906) [32], which is,

Definition 2.1. A point $x^*$ is Pareto efficient iff there does not exist another point $x$, such that $F(x) \geq F(x^*)$ with at least one $F_i(x) > F_i(x^*)$. Otherwise, $x^*$ is Pareto inefficient.

Definition 2.2. Pareto Frontier: The set of all Pareto efficient points is called the Pareto (efficient) frontier.

It would be important to note that Pareto efficiency itself does not imply equality or fairness in an economic system. In fact, a Pareto efficient status can be extremely unbalanced – that a few individuals may take a great share of the benefits, while the remaining ones possess only a small portion. As a result, we may need to take special consideration to find the economically favorable Pareto efficient solution to a system.

Definition 2.3. Pareto Improvement: A status from point $x_1$ to $x_2$ is called a Pareto improvement iff $F(x_1) \leq F(x_2)$ with at least one $F_i(x_1) < F_i(x_2)$.

Definition 2.4. Utopia Point: A point $F^*_1 \in \mathbb{R}^k$ is a utopia point iff for each $i = 1, 2, \ldots, k$, $F^*_i = \max_x F_i(x)$. The corresponding variable $x^*_i$ is the utopia decision variable.

Intuitively, a Pareto improvement is an action conducted in a system that harms no one and helps at least one person. Pareto improvements will keep adding to the economy until it achieves
3 PARETO EFFICIENT ECONOMIC RECOMMENDATION

We propose our Pareto Efficient Economic Recommendation (PEER) framework in this section. We first formalize the problem into an Online Resource Allocation (ORA) framework with multi-objective surplus maximization, and further propose methods to estimate the personalized utility and surplus with economic theories.

3.1 Problem Formalization

Suppose there exist m users \{u_1, u_2, \ldots, u_m\} in an online economic system, and there are n items \{v_1, v_2, \ldots, v_n\} to be allocated among the users, where the maximum quantity of each item consists the quantity vector \(q = [q_1, q_2, \ldots, q_n]^T\). In the following, we use \(1 \leq i \leq m\) and \(1 \leq j \leq n\) to index the users and items, respectively.

The Online Resource Allocation (ORA) [52] problem aims to find an allocation matrix \(Q = [Q_{ij}]_{m \times n}\), where \(Q_{ij} \geq 0\) is the quantity that user \(u_i\) is provided with item \(v_j\), under the maximum quantity constraint of \(\sum_{i=1}^{m} Q_{ij} \leq q_j, \forall j\).

Pareto efficient recommendation thus attempts to provide recommendations according to the Pareto efficient allocation of the online services in terms of per-user benefits (i.e., surplus). Let \(Q_i\) be the allocation vector for user \(u_i\) so that \(Q = [Q_1 Q_2 \cdots Q_m]^T\), and let \(S_i(Q_i)\) be the surplus that user \(u_i\) achieves from his/her allocated items. We aim to solve the following MOO problem,

\[
\begin{align*}
\max_{Q=[Q_{ij}]_{m \times n}} & \quad S(Q) = [S_1(Q_1), S_2(Q_2), \ldots, S_m(Q_m)]^T \\
\text{s.t.} & \quad Q_{ij} \geq 0, \quad i = 1, 2, \ldots, m \\
& \quad \sum_{i=1}^{m} Q_{ij} \leq q_j, \quad j = 1, 2, \ldots, n
\end{align*}
\]

(4)

which maximizes the surpluses of different users jointly. The model produces Pareto efficient allocations on user benefits, which are taken to make system decisions.

3.2 Model Specification

The key to specifying the mathematical form of Eq.(4) is to calculate the per-user surplus \(S_i(Q_i)\) given an arbitrary allocation matrix \(Q_i\). Let \(P_j\) be the price of item \(v_j\), which is pre-known, we have,

\[
S_i(Q_i) = \sum_{j=1}^{n} S_i(Q_{ij}) = \sum_{j=1}^{n} [U_i(Q_{ij}) - P_j \cdot Q_{ij}]
\]

(5)

where \(U_i(\cdot)\) is the utility of user \(u_i\) on item \(v_j\). It is important to notice that the utility function \(U_i(\cdot)\) is personalized – that different users may gain different utilities even on the same quantity of the same item. This is because of the different preferences of users, namely, a product favored by this user may not be quite favored by another one, and this nature serves as the inherent driving power for personalized recommendation.

In this work, we estimate the personalized utility \(U_{ij}(q)\) per user-item level to represent the personalized user preference on each item. Specifically, the utility for different user-item pairs share the same form but are parameterized by different parameters:

\[
U_{ij}(q) = a_{ij} \ln(1 + q) + (\alpha + \beta_i + y_{ij} + u_j^T v_j) \ln(1 + q)
\]

(6)

where the risk aversion parameter \(a_{ij}\) is re-parameterized in the spirit of collaborative filtering: \(\alpha, \beta_i, y_{ij}\) are the global, user, and item offsets; and \(u_i, v_j \in \mathbb{R}^k\) are the user and item representation vectors, respectively.

As a result, the calculation of per-user surplus boils down to the estimation of per-user-item utility function \(U_{ij}(q)\).

3.3 Personalized Utility Estimation

Similar to [52], we conduct personalized utility estimation based on the observed user purchasing records. Let \(q_{ij}\) be the quantity that user \(u_i\) purchased item \(v_j\), and \(S_{ij}(q_{ij}) = U_{ij}(q_{ij}) - P_j q_{ij}\) be the surplus that user \(u_i\) gains from this purchase. Then the Law of Zero Surplus for the Last Unit [13] in economics states that,

\[
\Delta S_{ij}(q_{ij}) = S_{ij}(q_{ij}) - S_{ij}(q_{ij} - 1) \geq 0
\]

(7)

Intuitively, it means that the reason a user purchases a quantity of \(q_{ij}\) on an item, is that he/she can still obtain increased surplus with the last unit, but even a single more unit of purchase will decrease the surplus. With this, we maximize the following log-likelihood of observing the whole purchasing records dataset \(D\),

\[
\max_{\Theta} \log p(D) = \sum_{i=1}^{m} \sum_{j=1}^{n} I_{ij} \left( \Pr(\Delta S_{ij}(q_{ij}) \geq 0) \Pr(\Delta S_{ij}(q_{ij} + 1) < 0) \right) - \lambda ||\Omega||_F^2
\]

(8)

where \(\Omega = \{a, \beta_i, y_{ij}, u_i, v_j\}^{m \times n}\) is the parameter set, \(I_{ij}\) is an indicator whose value is 1 when user \(u_i\) purchased item \(v_j\) in the dataset and 0 otherwise, \(\lambda > 0\) is the regularization coefficient, and \(u_i, v_j \in \mathbb{R}^k\) are non-negative. We adopt the commonly used sigmoid function to model the probabilities:

\[
\Pr(\Delta S_{ij}(q_{ij}) \geq 0) = \frac{1}{1 + \exp(-\Delta S_{ij}(q_{ij}))}
\]

(9)

We optimize Eq.(8) by Stochastic Gradient Descent (SGD) to get the optimal parameter set \(\Theta\), thus obtain the per user-item utility functions \(U_{ij}(q) = (\alpha + \beta_i + y_{ij} + u_i^T v_j) \ln(1 + q)\).

3.4 MOO Scalarization

Given utility functions \(U_{ij}(q)\), prices \(P_j\), and quantity constraints \(q = [q_1, q_2, \ldots, q_n]^T\), the MOO function in Eq.(4) is determined only on the allocation matrix \(Q = [Q_{ij}]_{m \times n}\).

Since its existence, researchers have proposed various approaches to multi-objective optimization, and they can be generally classified into a priori, a posteriori and interactive methods, which involve the preference information from the decision maker priorly, posteriorly, or interactively during the model learning process [28].

In this work, we adopt the a priori approach because we aim at an offline learning algorithm for Pareto efficient allocation. To
do so, we adopt the scalarization method to transform the multi-objective problem into a single-objective one. When scalarization is done neatly, Pareto optimality of the solutions obtained can be guaranteed [29]. It is proven that minimizing the following function is necessary and sufficient for Pareto optimality of Eq.(4) [28, 49]:

$$\begin{align*}
\text{minimize } & S(Q) = \sum_{i} w_i \left( S_i(Q_i) - S_i^0 \right)^2 \\
\text{s.t. } & Q_i \geq 0, \quad \forall i, j
\end{align*}$$

where $w_1, w_2, \ldots, w_m \geq 0$ are the weights set by the decision maker, whose relative values reflect the decision maker’s preference on the importance of each user. Mathematically, different choices of weights will result in different Pareto efficient optima, although many of them can be extremely unbalanced. Because we treat the benefits of each user equally and do not pose any special preference on specific users, we adopt identical weights $w_i = 1$ in this work.

$S^0_i$ is the Utopia point for user $u_i$, which is determined by the maximum possible surplus of the user. We already have:

$$S_i(Q_{ij}) = \frac{a_{ij}}{1 + Q_{ij}} - P_j Q_{ij} = a_{ij} \ln(1 + Q_{ij}) - P_j Q_{ij}$$

Let derivative be zero with respect to global quantity limits:

$$S_i'(Q_{ij}) = \frac{a_{ij}}{1 + Q_{ij}} - P_j = 0, \quad \forall r, s, Q_{ij} \leq q_j$$

We thus have the user decision variable $Q_i^0$ and utopia point $S_i^0$:

$$Q_i^0 = \min_i \left( \frac{a_{ij}}{P_j} - 1, q_j \right), \forall j = 1, 2, \ldots, n$$

$$S_i^0 = \sum_j \left( U_{ij}(Q_{ij}) - P_j Q_{ij} \right), \forall j = 1, 2, \ldots, m$$

With these components, we plug Eq.(5)(6)(13) and $w_i = 1$ into Eq.(10) for model specification.

### 3.5 Model Learning

We transform Eq.(10) into a non-constrained problem with penalties, so that it can be conveniently solved with gradient optimization. More concretely, we transform the two constraints into penalty terms added to the objective to penalize infeasible solutions:

$$\begin{align*}
\text{minimize } & L(Q) = \sum_{i} \left( \sum_j \left( a_{ij} \ln(1 + Q_{ij}) - P_j Q_{ij} - S_i^0 \right) \right)^2 \\
-\lambda_1 \sum_i \log(Q_{ij}) - \lambda_2 \sum_j \min_j \{0, q_j - \sum_i Q_{ij}\}
\end{align*}$$

where the second term is the log-barrier function that prevents the elements in $Q$ from approaching the nonnegative cone, and the last term is a hinge-loss that penalizes an allocation that violates the quantity constraint. One may also use the hinge-loss $-\lambda_3 \sum_i \min_j \{0, Q_{ij}\}$ for $Q \geq 0$, but this would give sparse optima, which are not favored in this work because we rely on the result allocation matrix $Q$ to rank all the items for each user.

In Eq.(14), $\lambda_1, \lambda_2 \in \mathbb{R}^+$ determine the tradeoff between the accuracy of the approximation procedure and the feasibility of the solution. With $\lambda_1$ and $\lambda_2 \to \infty$, any violation of the constraints will be greatly penalized and the solution is guaranteed to be in the feasible region. However, the objective term maybe dominated by these two penalty terms, causing the solution to be inaccurate.

To combine the best of two worlds, we propose a sequential minimization framework: for each fixed pair $(\lambda_1, \lambda_2)$, we optimize Eq.(14) to find a local minimum solution $Q(\lambda_1, \lambda_2)$ which depends on the current $(\lambda_1, \lambda_2)$, then we increase the parameters $(\lambda_1, \lambda_2)$ by a factor $\mu > 1$ and restart the optimization with $Q(\lambda_1, \lambda_2)$ as the initial point. To increase the approximation accuracy when $\lambda_1$ and $\lambda_2$ get larger, we increase the number of steps per iteration, ensuring that the penalty terms will vanish as the solution becomes feasible, and the objective term will get fully optimized. The process is repeated until the current solution is a stationary point.

To apply the sequential minimization framework, we derive the gradient for Eq.(14), where $\nabla_1 Q^1, \nabla_2 Q^2, \nabla_3 Q^3$ denote the gradient for each of the three additive components:

$$\begin{align*}
\nabla_1 Q^1 &= 2 \left( \sum_j \left( S_i(Q_{ij}) - S_i^0 \right) \left( \frac{a_{ij}}{1 + Q_{ij}} - P_j \right) \right)_{m \times n} \\
\nabla_2 Q^2 &= -\lambda_1 \left[ \frac{1}{Q_{ij}} \right]_{m \times n} \\
\nabla_3 Q^3 &= -\lambda_2 \left( 1_{m} \cdot q_i - a_{ij} \right)_{m \times n}
\end{align*}$$

where $1_m$ is a column vector of 1’s, and $1_{m \times n} q_i$ is the indicator function $1_{x < 0}$ applied to every element of the vector $q^T m$. As a result, the gradient of Eq.(14) will be:

$$\nabla_1 L(Q) = \nabla_1 Q^1 + \nabla_2 Q^2 + \nabla_3 Q^3$$

However, the huge number of users and items in practice makes it computationally infeasible to directly gradient on the allocation matrix $Q$. As a result, we still re-parameterize the allocation matrix according to the spirit of collaborative filtering, i.e., let

$$Q_{ij} = a^i + \beta^i + \gamma^j + u_i^T v_j$$
where $\Theta = \{a', \beta_i', y_i', u_i', v_j'\}_{i,j=1,\ldots,m}$ is the parameter set, and $u_i', v_j' \in \mathbb{R}^k$ are latent vectors. As a result, $Q$ becomes an intermediate parameter and the gradient on low-dimensional parameters $\Theta$ is:

$$
\nabla_\Theta L(\Theta) = \nabla_Q L(Q) \cdot \nabla_\Theta = (\nabla_Q^1 + \nabla_Q^2 + \nabla_Q^3) \cdot \nabla_\Theta Q
$$

(18)

Once we obtain a closed form solution to compute the gradients, we can apply various kinds of unconstrained minimization algorithms, e.g., gradient descent, conjugate gradient or L-BFGS [3]. For illustrative purposes, we provide an algorithm using gradient descent in Algorithms 1. Assuming the algorithm will perform $r$ iterations in each inner loop, the time complexity of Algorithm 1 is $O(rmn \log p_{\text{max}}(\frac{1}{r}))$.

With the Pareto efficient allocation matrix $Q^*$ produced by the algorithm, we can thus provide the following Pareto improvement list for each user $u_i$, ranking the items $v_j$ in descending order of the quantity $Q^*_{ij}$ allocated to him/her.

4 PARETO IMPROVEMENT PROCESS

Researchers have developed many successful personalized recommendation algorithms, which are widely applied to various practical systems. Taking advantages of their insightful designs can be beneficial to both the practitioners and recommendation results.

Although they do not primarily consider Pareto efficiency of the recommendations, their results can be promoted into Pareto efficient ones, which improves the user benefits, and meanwhile keeps a satisfactory recommendation performance. To this end, we propose a Pareto Improvement Process (PIP) in this section.

We first construct the replication allocation matrix $\hat{Q}$ from the recommendation results of a given recommendation algorithm. Let the top-$K$ recommendation list for user $u_i$ given by the algorithm be $R_i = \{v_{i1}, v_{i2}, \ldots, v_{ik}\}$, we construct the corresponding recommendation vector $r_i = [v_{ij}, j \in R_i]_{1 \times K}$, where the $j$-th element is 1 if the $j$-th item is in the recommendation list, and 0 otherwise. With the vectors for all users, we have $\hat{Q} = [r_1; r_2; \ldots; r_m]^\top$.

Note that $\hat{Q}$ may not satisfy the quantity constraint $q = [q_1, q_2, \ldots, q_n]^\top$. To make it feasible, we examine each column of $\hat{Q}$, and if $\sum_{i=1}^m \hat{Q}_{ij} > q_j$, we only retain a total number $q_j$ of $1$’s in that column. These $1$’s correspond to the users whose recommendation list $R_i$ ranks item $v_j$ in higher position, i.e., we allocate the limited number of item $v_j$ to those users who better prefer the item. To help with a clearer understanding, we present the procedure in Algorithm 2.

Based on the replication allocation matrix $\hat{Q}$, we calculate the current benefit $\hat{S}_i = S_i(\hat{Q})$ for each user $u_i$, and further solve the following Pareto improvement problem:

$$
\begin{align*}
\text{maximize} & \quad S(Q) = [S_1(Q), S_2(Q), \ldots, S_m(Q)]^\top \\
\text{s.t.} & \quad Q_{ij} \geq 0, \quad Q_{ij} \leq q_j, \quad S_i(Q) \geq \hat{S}_i, \quad \forall i, j
\end{align*}
$$

(19)

where the third constraint is incorporated to guarantee Pareto improvements.

Algorithm 2: Replication Matrix Construction

| Input: Top-K recommendation list $R_i = \{v_{i1}, v_{i2}, \ldots, v_{ik}\}$ for each user $u_i$, quantity constraint $q = [q_1, q_2, \ldots, q_n]^\top$ |
| Output: Replicate allocation matrix $\hat{Q}$ |

1. for each user $u_i$ ($i \leftarrow 1$ to $m$) do
2. $r_i \leftarrow [v_{ij}, j \in R_i]_{1 \times K}$: //identification vector
3. $p_i \leftarrow [\infty]_{1 \times K}$: //ranking position vector
4. for each item $v_j$ ($j \leftarrow 1$ to $n$) do
5. if $v_j \in R_i$ and $v_j \equiv v_{i\hat{r}}$ then
6. $p_{ij} \leftarrow \hat{r}$; //record the ranking position
7. $\hat{Q} \leftarrow [r_1, r_2, \ldots, r_m]^\top$;
8. for each item $v_j$ ($j \leftarrow 1$ to $n$) do
9. if $\sum_{i=1}^m \hat{Q}_{ij} > q_j$ then
10. Rank users ($u_i$’s) in ascending order of $p_{ij}$;
11. Keep $\hat{Q}_{ij} = 1$ for top-$q_j$ users and change the remaining to 0;
12. return $\hat{Q}$;

Similarly, Eq.(19) can be scalarized and further converted into the following non-constrained optimization problem:

$$
\begin{align*}
\text{minimize} & \quad \hat{L}(Q) = \sum_i \left( S_i(Q) - S^*_i \right)^2 - \lambda_1 \sum_j \log(Q_{ij}) \\
& - \lambda_2 \sum_j \min \left( 0, q_j - \sum_i Q_{ij} \right) - \lambda_3 \sum_i \min \left( 0, S_i(Q) - \hat{S}_i \right)
\end{align*}
$$

(20)

where the gradient for the last term is:

$$
\nabla^4_{\hat{Q}} = -\lambda_3 \left( [S(Q) - \hat{S} < 0] \cdot 1_n^\top \right)
$$

(21)

With the gradients $\nabla_{\hat{Q}} L(\hat{Q}) = \nabla^1_{\hat{Q}} + \nabla^2_{\hat{Q}} \cdot \nabla^3_{\hat{Q}}$ and $\nabla_{\Theta} L(\Theta) = \nabla_Q L(Q) \cdot \nabla_{\Theta} Q$, we can still adopt Algorithm 1 for model learning, and take the output Pareto efficient allocation matrix for personalized recommendation.

5 DISCUSSIONS

We further discuss some of the properties of the Pareto efficient economic recommendation framework and Pareto improvement process.

We can see that when $q_j = \infty$ ($V_j$) in Eq.(4), the quantity constraint components in Eq.(10)(14) (19)(20) all vanish, and $\nabla_{\hat{Q}}^4 = 0$ in Eq.(15). As a result, the model learning process automatically turns into a non-constrained one. Besides, the surplus $S_i(Q)$ that each user achieves from an allocation are no longer mutually correlated in this case, thus the Pareto efficient model learning actually maximizes the surplus of each user independently, and reaches the utopia points. As a result, the quantity constraints (i.e., limited resource allocation) serve as the critical component to bridge the relationship of different users, because the allocation of an item to one user may imply that other users are neglected, which is similar to our physical economic world.

Except for the consumer surplus (i.e., utility beyond price: $U(q) - Pq$) that we have considered in this work, economists have also studied producer surplus, i.e., price beyond cost: $Pq - c$, where $c$ is
the per-item cost. In this work, we do not incorporate producer surplus into consideration for total surplus maximization (as [52]) for two reasons, 1) the producer surplus will mathematically be a fixed value when all items are allocated out, and 2) the price component \((Pq)\) offsets when adding the producer and consumer surplus for total surplus maximization, as a result, some users may be sacrificed for the maximization of collective interest (total surplus), which is philosophically not favored. In this work, however, we guarantee that each user benefits and no one has to sacrifice for the whole economic system.

As stated before, the weight parameters \(w_i\) in Eq(10) determine the distribution of benefits among users, and different choices of \(w_i\) lead to different Pareto efficient allocations. Although we choose to treat users equally by setting identical \(w_i\)'s in this work, we can actually control the distribution of benefits among different users with different weights, so as to achieve targeted (but still Pareto efficient) allocations for specific business intelligence goals in real-world systems.

6 EXPERIMENTS
We conduct extensive experiments to evaluate the performance of both the Pareto Efficient Economic Recommendation (PEER) and Pareto Improvement Process (PIP), in terms of recommendation performance, economic efficiency, and Pareto efficiency.

6.1 Dataset Description
We take the user purchasing records dataset from Shop.com for experiments, because two of the most important information sources needed in our framework are the price of items and quantity of purchasing, which are absent in many of the other datasets. To avoid the problem of cold-start [23, 51] so as to focus on our key research target of Pareto efficient recommendation, we select those users and items of at least five purchasing records, which is a frequently adopted pre-processing method in previous work [22, 23, 46]. Some statistics of our dataset are summarized in Table 1.

<table>
<thead>
<tr>
<th>Table 1: Statistics of the Shop.com dataset</th>
</tr>
</thead>
<tbody>
<tr>
<td>#Consumers</td>
</tr>
<tr>
<td>34,099</td>
</tr>
</tbody>
</table>

For experimental purpose, we randomly select 75% of the transactions from each user to construct the training set, and adopt the remaining transactions as testing set for evaluation. This amounts to around 100k transactions from 34k users towards 30k items in the testing set.

6.2 Experimental Setup
We set the initial penalty parameters \(\lambda_1^{(0)} = \lambda_2^{(0)} = 0.1\), step factor \(\mu = 2\), initial learning rate \(\gamma^{(0)} = 0.1\), threshold \(\epsilon_1 = \epsilon_2 = 0.1\), and dimension of latent factors \(k = 20\) in Algorithm 1. In the experiments, we aim to provide and evaluate top-N recommendation lists for users, where \(N\) runs from 1 to 50. As a result, we set the length of recommendation list \(K = 50\) when constructing the replication allocation matrix in Algorithm 2, so that the baselines get fair (or even better) treatment.

When estimating the personalized utility function in Eq.(8), we set \(\lambda = 0.05\) and the dimension of representation vectors \(u_i, v_j \in \mathbb{R}^k\) as \(k = 20\), because we find that 20 factors are sufficiently enough to stable the model performance.

We take the following representative and state-of-the-art recommendation algorithms for performance comparison:

- **NMF**: Non-negative Matrix Factorization [21], which is a representative and one of the most frequently used matrix factorization approach for personalized recommendation. To apply, we construct the user-item purchasing quantity sparse matrix and predict the missing values, based on which to provide personalized recommendation list for each user in descending order of the predictions.
- **BPRMF**: Bayesian Personalized Ranking with Matrix Factorization [34] that is one of the state-of-the-art approaches for ranking-based recommendation. In implementation, we conduct balanced negative sampling on un-purchased items for model learning.
- **TSM**: Total Surplus Maximization [52] approach that maximizes the total (i.e., consumer plus producer) surplus of an economic system for service allocation and recommendation. It is a state-of-the-art economic surplus-based approach for recommendation.

For each approach we carefully tune the parameters to achieve the best performance. In NMF and BPRMF, we select 20 factors with regularization coefficient \(\lambda = 0.1\), and for TSM we also use 20 factors and use \(\lambda = 0.05, \eta = 5\) for regularization. In the following, we use PEER to represent our Pareto Efficient Economic Recommendation approach proposed in this work. Besides, we also apply our Pareto Improvement Process (PIP) on three of the baselines for evaluation, which are denoted as PIP-NMF, PIP-BPRMF, and PIP-TSM in the following, respectively.

We adopt different evaluation metrics for different experimental tasks, which will be exposited in each of the following subsections.

6.3 Recommendation Performance
We first evaluate the performance on personalized recommendation for each approach. To do so, we construct top-N recommendation list for each user in the testing set based on each algorithm, and take the Conversion-Rate@N (CR@N) for evaluation.

For a set of testing users and the top-N recommendation list for each of them, CR@N is the percentage of lists that ‘hit’ the purchase records in the testing set of the target user. In our experiment, \(N\) runs from 1 to 50 with a step of 5. For each user in the testing set, there are as many as 30k candidate products for recommendation, and all the candidate products are present in the training dataset. For computational efficiency, we randomly select 1000 users to evaluate average CR at each time, and the CR performance of 30 testing rounds are averaged to provide the final evaluation results.

Figure 1(a) shows the experimental results of each algorithm, and more specific numbers on typical choices of \(N\) are shown in Table 2. We see that our PEER approach generally gains better performance than traditional algorithms (NMF and BPRMF). On considering that the key different of PEER from previous algorithms is to model user preferences with economic basis (personalized utility and surplus...
We evaluate the economic efficiency of the proposed algorithm, which is defined as follows:

\[
CS@N = \frac{1}{M} \sum_{i=1}^{M} \sum_{j \in \Pi_{i,N}} (a_{ij} \ln(1 + Q_{ij}) - P_j Q_{ij})
\]

where \(i\) and \(M\) are the index and the total number of testing users, \(N\) is the length of recommendation list, and \(\Pi_{i,N}\) is the recommendation list for the \(i\)-th user. For fair comparison between algorithms, we take \(Q_{ij} = 1\) for the recommended items, which means that a user will finally purchase one for each item in the recommendation list. Figure 1(b) shows the results on averaged consumer surplus v.s. the length of recommendation lists, and detailed results on selected recommendation lengths are displayed in Table 2.

We see that the average consumer surplus is significantly boosted by the Pareto Improvement Process (PIP) on traditional recommendation algorithms of NMF and BPRMF, which validates the effectiveness of our PIP approach in the economic efficiency of traditional algorithms. However, we also observe that PIP does not achieve significant improvement on TSM. The underlying reason can be that TSM is also designed with a philosophy of surplus maximization. Although it attempts to maximize the joint surplus of both producers and consumers, it has indeed taken the benefit of users into consideration. Nevertheless, by maximizing the joint consumer surplus in a direct manner, the PEER approach gains the best performance on economic efficiency in terms of accumulated consumer surplus.

Besides, we see that the \(CS@N\) of NMF and BPRMF increases approximately linearly with the increase of recommendation length \(N\), while in the surplus-driven approaches (e.g., PEER, TSM, PIP-TSM), \(CS@N\) tends to increase with diminishing marginal increments. This shows that the surplus-driven approaches are able to rank those items of higher surplus for users to top positions in the list, while traditional algorithms tend to distribute the items according to the consideration of price and quantity, this implies the effectiveness of principled economic basis in business intelligence.

Another observation is that PEER also outperforms TSM, which is interesting because the allocation results produced by TSM is in fact also a Pareto efficient solution, while the difference is that TSM takes producer surplus into consideration for allocation of benefits. This observation verifies the economic intuition that producers and consumers have conflicts of interest in the allocation of total internet welfare (surplus), so that each party has to "steal" surplus from the other side so as to benefit themselves. As a result, maximizing the benefits of consumers alone (instead of together with producers) helps consumers to gain better experience.

We also see that the PIP-boosted algorithms are generally better than their corresponding non-PIP version, which is not surprising because we re-optimize their outputs to better align with the personalized utilities of users for Pareto efficiency. But what is surprising is that they did not significantly outperform the randomly initialized PEER approach.

More detailed examinations show that the recommendation lists of NMF and BPRMF lead to heavily unbalanced service allocations among different users after processing by Algorithm 2, that those active users tend to possess much higher surplus than inactive users. This is because the inactive users are usually recommended with the similar (mostly popular) items, so that they have to compete for the limited benefits from these items. As a result, the optimization procedure of Algorithm 1 will finally converge into unbalanced Pareto efficient solutions. But because TSM has already taken user balance into consideration, its PIP-boosted version achieves comparable performance with PEER.

### 6.4 Economic Efficiency

We evaluate the economic efficiency of the proposed algorithm in this section. To do so, we calculate the accumulated consumer surplus of a top-\(N\) recommendation list and average across the users, which is defined as follows:

\[
CR@N = \frac{1}{M} \sum_{i=1}^{M} \sum_{j \in \Pi_{i,N}} (a_{ij} \ln(1 + Q_{ij}) - P_j Q_{ij})
\]

where \(i\) and \(M\) are the index and the total number of testing users, \(N\) is the length of recommendation list, and \(\Pi_{i,N}\) is the recommendation list for the \(i\)-th user. For fair comparison between algorithms, we take \(Q_{ij} = 1\) for the recommended items, which means that a user will finally purchase one for each item in the recommendation list. Figure 1(b) shows the results on averaged consumer surplus v.s. the length of recommendation lists, and detailed results on selected recommendation lengths are displayed in Table 2.

We see that the average consumer surplus is significantly boosted by the Pareto Improvement Process (PIP) on traditional recommendation algorithms of NMF and BPRMF, which validates the effectiveness of our PIP approach in the economic efficiency of traditional algorithms. However, we also observe that PIP does not achieve significant improvement on TSM. The underlying reason can be that TSM is also designed with a philosophy of surplus maximization. Although it attempts to maximize the joint surplus of both producers and consumers, it has indeed taken the benefit of users into consideration. Nevertheless, by maximizing the joint consumer surplus in a direct manner, the PEER approach gains the best performance on economic efficiency in terms of accumulated consumer surplus.

Besides, we see that the \(CS@N\) of NMF and BPRMF increases approximately linearly with the increase of recommendation length \(N\), while in the surplus-driven approaches (e.g., PEER, TSM, PIP-TSM), \(CS@N\) tends to increase with diminishing marginal increments. This shows that the surplus-driven approaches are able to rank those items of higher surplus for users to top positions in the list, while traditional algorithms tend to distribute the items according to the consideration of price and quantity, this implies the effectiveness of principled economic basis in business intelligence.

Integrating the consideration of price and quantity, this implies the effectiveness of principled economic basis in business intelligence.
to the probability of user likeness, with little consideration of the amount of benefits that an item brings to a user.

### 6.5 Pareto Efficiency

We also care about the Pareto efficiency of the recommendation (allocation) results, which measures the degree that a Web economic system is close to its best possible efficient resource allocation status. To do so, we calculate the averaged Percentage Utopia Surplus (PUS) when a top-$N$ recommendation list is provided to each user: 

$$PUS@N = \frac{1}{M} \sum_{i=1}^{M} \left( S_i(Q_N)/S_i^Q \right)$$

where $Q_N$ is the allocation matrix corresponding to the top-$N$ recommendation lists of $M$ testing users – that each recommended item is allocated with a quantity of one to its corresponding user. We also calculate the PUS value given the directly estimated allocation matrix $Q$ for those applicable algorithms (i.e., PEER, PIP-X, and TSM), and this result is shown as $PUS_Q$ in Table 2.

We see that the PEER approach generally gains the best $PUS@N$ performance on most selections of recommendation length $N$, but the results are not statistically significant except $N = 20$ and against NMF or BPRMF, because the consumer surplus is too small when only a few (i.e., $N$) items are provided. However, results become clearer when we do not limit the number of provided items, and evaluate PUS on the output allocation matrix $Q$ directly, as shown in the last column of Table 2. Note that the NMF and BPRMF algorithms do not produce any allocation matrix directly, so the $PUS_Q$ measure is not applicable to them.

It is seen that PIP-NMF/BPRMF did not achieve satisfactory PUS even after promoting by PIP. Detailed examinations indicate that this is also due to the unbalanced initial allocations given by NMF/BPRMF, so that some users possess very high initial surplus. Per the nature of Pareto improvement that avoids hurting anyone, those users dominate the allocations so that other users eventually gain only small surplus values, leading to low average PUS results. In contrast, by treating consumer surplus in a balanced manner, TSM gives better initial surpluses and the PUS can be further promoted by the PIP framework. Finally, by optimizing the consumer surpluses toward utopia points directly, the PEER approach gains significantly the best average PUS – which when combined with the observed improvement from TSM to PIP-TSM – verifies the Pareto efficiency of our proposed optimization algorithms.

### 7 RELATED WORK

The efficiency of economic systems has long been a vitally important research consideration in economics [4], especially in welfare economics [16]. Ever since the existence of human social production in ancient ages, people have been considering the proper, acceptable, and mutually beneficial ways for allocation of resources [42]. The breakthroughs of human production capability brought about by the first and second Industrial Revolution has further driven the human society to rethink about the ways to efficiently allocate goods, capital, energy, and various other types of resources [39].

Although philosophically debated among economists for centuries [30], it was not until the 1900’s that economic efficiency were proposed to be clearly and objectively measured – which is called the Pareto criterion named after Italian economist Vilfredo Pareto (1848-1923) [32], stating that an efficient status should be a situation in which it is impossible to make anyone better-off without making someone worse-off. Pareto efficiency (or Pareto optimality) has been one of the most basic concepts in mainstream economics, and it is widely used to analyze and optimize the resource allocation in economic and engineering systems [28].

However, although the Web has shaped into a tremendous online economy by continuously integrating human activities from offline to online, the research community has seldom considered the Pareto efficiency of the Web from an economic point of view. Actually, many of the Web-based services can be formalized into the classical producer-consumer economic paradigm [52], where consumers/users consume normal goods, financial products, jobs, or news feeds from producers in E-commerce [20], online financing [9, 26], crowd-sourcing [15, 17], or news portals [24], etc. By implicitly assigning certain items to targeted users in technical forms of personalized recommendation [18, 37] or search [7, 43], the Web actually serves a fundamental role in resource allocation on the massive online economy.

Nevertheless, traditional Web-based approaches mostly make allocations to match the preference of each individual user, without treating the system as a whole to examine the mutual influence between user benefits. For example, both the Collaborative Filtering (CF)-based [11, 19, 41], Content-based [25, 33], or hybrid [8] recommendation approaches adopt meticulously designed algorithms to model user preferences, but the recommendation of an item to one user does not pose effect to others. This lack of economic system-wise view leads to the Pareto inefficiency of recommendation/allocation results.

Recent research lines have begun to tackle the problem. [52] proposed economic recommendation by automatically estimating the utility and surplus for each user-item pair from large-scale Web data, such as consumer purchasing logs and online transactions. Based on this, [53] further extended the work to multiple product (i.e., product set) utility estimation, so that we can calculate the utility of a combination of products by considering their complementary and substitutive relationships.

It is worthwhile to note that, as a frequently used optimization strategy, Multi-Objective Optimization and the Pareto optimization principle have been applied to plenty of research in recommender systems [1, 2, 27, 31, 35, 36, 40, 48], but the related research mostly focus on jointly maximizing mutually unaligned recommendation objectives, e.g., accuracy, novelty, and diversity, etc. In this work, however, we focus on the economic interpretation of recommender systems, aiming to quantify and maximize the consumer surplus (welfare) with MOO from an economic point of view to model the online economy, which is different from the motivation of previous MOO-based research.

### 8 CONCLUSIONS AND FUTURE WORK

Existing approaches of recommender systems focus on providing targeted recommendations to match the preference of each individual user. Although many Web applications have turned into intact online economic systems, little consideration is put on the essential problem of online economic efficiency – that why and how Web-based systems can achieve efficient service allocations.
This paper attempts to answer these principled questions based on established economic theories melded with solid data-driven algorithmic approaches. To do so, we first formalized the online resource allocation problem that serves as the basic functionality of most Web-based systems, and further proposed algorithms to measure the user benefits in terms of utility and surplus. Based on this, we proposed Pareto efficient economic recommendation that attempts to find the Pareto optimal service allocation of the system with consideration of mutual correlations among users. To benefit the many existing personalized recommendation algorithms, we further proposed the Pareto improvement process to re-optimize their recommendation results into Pareto efficient ones. Experimental results on real-world industry data verified the proposed approaches in terms of recommendation performance, consumer surplus, and Pareto efficiency.

This is our first step towards an economic efficient Web, and there is much room for further improvements. In the future, we will study different utility functions in measuring consumer surplus. We can compute other Pareto efficient solutions beyond the balanced one to get the Pareto frontier and investigate their differences. More importantly, our basic philosophy to promote Web efficiency is not restricted to e-commerce, and it can well be generalized to various other Web services, which is promising to both interdisciplinary research and practical applications.
